Abstract. Full jet reconstruction in relativistic heavy ion collisions provides new and unique insights to the physics of parton energy loss. Because of the large underlying event multiplicity in $A + A$ collisions, random and correlated fluctuations in the background can result in the reconstruction of fake jets. These fake jets must be identified and rejected to obtain the purest jet sample possible. A large but reducible fake rate of jets reconstructed using an iterative cone algorithm on HIJING events is observed. The absolute rate of fake jets exceeds the binary-scaled $p + p$ jet rate below 50 GeV and is not negligible until 100 GeV. The variable Σj_T , the sum of the jet constituent's E_T perpendicular to the jet axis, is introduced to identify and reject fake jets at by a factor of 100 making it negligible. This variable is shown to not strongly depend on jet energy profiles modified by energy loss. By studying azimuthal correlations of reconstructed di-jets, the fake jet rate can be evaluated in data.

1 Introduction

Complete jet reconstruction in relativistic heavy ion collisions is essential for a direct measurement of the energy lost by a high- p_T colored parton traversing the colored medium produced in these collisions. Measurements of such energy loss have been made from experiments at Brookhaven National Laboratory's (BNL) Relativistic Heavy Ion Collider (RHIC) where single particle production rates in $\sqrt{s_{NN}} = 200$ GeV $Au + Au$ collisions are suppressed relative to binary-collision scaled $p + p$ rates at the same $\sqrt{s}$ [1]. These measurements alone, however, are insufficient to constrain the details of the energy loss mechanism. For example, the current data cannot yet be used to determine the relative contributions of radiative and collisional energy loss, or even determine whether jet quenching is a perturbative or non-perturbative process. Because of the large underlying event multiplicity, $dN/d\eta \sim 600$ for the top 10% $Au + Au$ collision cross section [2], direct jet reconstruction at RHIC is difficult, though attempts are underway [3][4]. As a proxy for (di-)jet reconstruction, two, high- p_T particle azimuthal correlations have been measured. Results from two-particle correlations reveal that the trigger jet is essentially unmodified while the recoil jet is strongly suppressed [5], further lending support to the idea that parton energy loss is the mechanism of the suppression. However, two-particle correlations have not revealed expected modifications to jet properties [6] such as softening of the fragmentation function [7], broadening of the di-jet acoplanarity [8], etc. expected from energy loss models that reproduce the single particle

suppression. One possible reconciliation between the single particle and two-particle results is that the two-particle results are "energy loss biased". That is, by requiring that two high- p_T particles be present, events are chosen where the jet loses little, if any, energy. This can occur when the jet traverses a short path length [9] or emits no gluons due to fluctuations in radiation (punchthrough).

Direct measurements of jets reconstructed via standard algorithms employed in $p + \bar{p}(p)$ or e^+e^- collisions modified to handle the underlying heavy ion event, should reduce such energy loss biases. If the energy loss is dominated by gluon bremsstrahlung radiated predominantly inside the jet cone [10], the lost energy will be recovered by reconstructing the full jet profile. If, however, energy loss is non-perturbative [11] or radiates energy outside of the cone [12], a suppressed jet rate compared to binary-scaled $p + p$ will be observed. Whatever the scenario, direct measurements of jets will make a significant impact in understanding parton energy loss.

In the very near future the Large Hadron Collider (LHC) at CERN will deliver collisions of $Pb + Pb$ at $\sqrt{s_{NN}} = 5.5$ TeV. At this energy and nominal delivered luminosity, 20 million jets with $E_T > 50$ GeV will be produced per month of $Pb + Pb$ running [13]. These jets should be visible above the large underlying event multiplicity and can be reconstructed by jet reconstruction algorithms appropriately modified to handle the underlying event.

The ATLAS experiment will carry out extensive measurements of jet production in heavy ion collisions using its nearly hermetic electromagnetic and hadronic calorime-

Fig. 1. Comparison of the spectrum of jets in $dN/d\eta=2700$, $b=2$ fm, HIJING events. The (blue) filled circles are the expected spectrum from binary-scaled $p + p$, the diamonds are the raw reconstructed spectrum uncorrected for jet reconstruction efficiency and energy resolution. The dashed line indicates the raw fake rate evaluated from hard-cut HIJING events. The (red) squares indicate the irreducible fake spectrum after rejection of the fake jets.

ters and its large acceptance silicon tracking system. Techniques have been developed for iterative cone jet reconstruction in heavy ion collisions in ATLAS [14]. These techniques require subtraction of the underlying event energy within the calorimeter prior to running the iterative cone jet algorithm (see Section 3). Fluctuations in the background remain after subtraction and a stable cone, defined by the algorithm, can be obtained from random or correlated background. In studying any aspect of jets and their modification, such fake jets must be tagged and removed from the data sample. It is, therefore, necessary to study the characteristics of fake jets so as to extract a sample of jets with high purity.

This article describes the techniques that have been developed to identify and reject fake jets with the ATLAS detector arising from fluctuations in the underlying heavy ion event. The article is outlined as follows. In Section 2 the relevant aspects of the ATLAS detector are defined. Section 3 presents the necessary details of jet reconstruction in heavy ion collisions in ATLAS and the identification of fake jets. This is followed by Section 4 where the results of fake jet detection are presented. A discussion of potential biases associated with the method of rejection and evaluation of rejection with data is given in Section 5.

2 The Atlas Detector

The ATLAS detector [15] is a large, multi-purpose, high energy physics experiment designed to detect rare processes in $p + p$ collisions at $\sqrt{s} = 14$ TeV at the LHC. ATLAS has also been shown to be an excellent detector for measurements of both high p_T and soft observables in heavy ion collisions [16]. The jet reconstruction described here is purely calorimetric. The ATLAS calorime-

ter is largely divided into a liquid argon (LAr) barrel electromagnetic calorimeter covering $|\eta| < 3.2$, a LAr forward hadronic calorimeter covering $3.2 < |\eta| < 5$ and a barrel tile hadronic calorimeter covering $|\eta| < 1.5$. Each calorimeter compartment is divided into longitudinal sections providing energy readout at different depths in the calorimeter. The barrel electromagnetic calorimeter is divided into 3 layers. The front “strip” layer, with approximately $6 X_0$, has a typical cell (single readout) segmentation of $\Delta\eta \times \Delta\phi$ of 0.003×0.1 . The middle layer, with $24 X_0$, has a cell size of 0.025×0.025 in $\Delta\eta \times \Delta\phi$. The barrel tile calorimeter has three layers with depth-dependent cell size; the first layer has 0.1×0.1 segmentation. For reconstructing jets, towers in a fixed grid of 0.1×0.1 in $\Delta\eta \times \Delta\phi$ are built from sums of cell energies in all layers.

3 Jet reconstruction and fake jet identification

To evaluate the expected jet reconstruction performance in heavy ion collision with the ATLAS detector, di-jet PYTHIA [17] events were embedded in HIJING [18] heavy ion events. The HIJING events (referred to as “unmodified”) were generated without jet quenching and *without* a maximum p_T cut on the hard scattering processes. The unmodified events result in correlated and fluctuating backgrounds from (mini-)jets, $c - \bar{c}$ and $b - \bar{b}$ production, and longitudinal string radiation all unsuppressed from the lack of quenching. The HIJING events containing embedded jets were propagated through the ATLAS detector using the GEANT4 software package, digitized to resemble raw data, and then processed by the standard ATLAS offline software chain.

Jet reconstruction was performed using a seeded iterative cone jet algorithm [19][20] with a seed tower energy of 5 GeV and a cone radius $R = \sqrt{\Delta\phi^2 + \Delta\eta^2} = 0.4$. On average, in unmodified HIJING events with $dN/d\eta=2700$, 150 GeV of background event E_T is contained within the cone. The method used to subtract the background is to

1. find regions of high energy in the calorimeter (potential jet regions)
2. calculate the average background E_T in the calorimeter for each longitudinal layer i and as a function of η , $E_T^{bkgr}(i, \eta)$, excluding the regions found in step 1
3. subtract $E_T^{bkgr}(i, \eta)$ from all cells
4. build the 0.1×0.1 grid of calorimeter towers from these modified cells.

The subtracted towers from this procedure are provided as input to the seeded cone jet algorithm.

Figure 1 shows the invariant yields of jets in $b = 2$ fm, $dN/d\eta = 2700$, HIJING events. The solid (blue) circles indicates the binary-scaled $p + p$ jet rate obtained from PYTHIA. The diamonds show the reconstructed spectrum, including embedded PYTHIA jets and fake jets which survive fake jet rejection (see Section 4). The reconstructed spectrum is uncorrected for efficiency, energy

Fig. 2. Reconstructed jets with $E_T=57$ GeV from PYTHIA embedded into unmodified HIJING (left) and from hard-cut HIJING (right). The jet from the hard-cut HIJING is fake since no jets of this energy should exist in this sample (see text).

scale, and energy resolution. The need for these corrections is clear below 70 GeV while the reconstructed and expected spectra agree well above 70 GeV. For these high-multiplicity HIJING events, 70 GeV jets have a reconstruction efficiency of 70%, an energy scale offset of -2.5%, and an energy resolution of 25%. A complete evaluation of the centrality and E_T -dependence of the reconstruction is given in Ref. [14].

Fake jets were produced by generating, simulating in ATLAS, and performing jet reconstruction on a second set of HIJING events, labeled “hard-cut”. These events differ from the unmodified HIJING events in that the parton spectrum at $Q^2 > 100$ GeV² is not sampled. Therefore, jets with $E_T > 10$ GeV are purposefully suppressed with the intent being that any jet with $E_T \gg 10$ GeV is a fake jet. Even with a hard cut, jets above 10 GeV can occur from initial and/or final state radiation. What was also found was that longitudinal strings can radiate into midrapidity resulting in 10^{-2} jets with $E_T > 50$ GeV per event. These were removed from the fake jet sample by excluding jets which match a HIJING parton above an appropriate threshold.

The resulting reconstructed jets from the hard-cut HIJING events then define the “maximal” fake rate plotted in Figure 1. The rate of fake jets exceeds that of the expected jet yield at low- E_T . The ratio of fake to reconstructed yields is 4.2 at 50 GeV, 0.33 at 70 GeV, and 0.03 at 90 GeV. This shows that the contribution of fake jets decreases dramatically with reconstructed jet E_T . However, if it is desired to measure jets at moderate E_T , a rejection procedure is needed.

It is possible that the fake rate is overestimated. Part of the hard particle production in HIJING results from longitudinal strings, color fields between the nuclei, which, because of their large energy at the LHC, can fragment

into a jet at midrapidity. Although an attempt was made to remove such jets from the hard-cut events, a sample of hard-cut HIJING events with the longitudinal string radiation suppressed was also studied. The maximal rate was reduced such that the ratio of the fake to reconstructed yield is 1.5 at 50 GeV, 0.11 at 70 GeV, and 0.01 at 90 GeV. The longitudinal radiation, however, did not change the characteristics of the fake jets that were produced, nor their subsequent identification and rejection.

Fig. 3. The reconstructed jet E_T dependence of Σj_T for fake jets from the unmodified HIJING sample (circles) and for reconstructed embedded jets in $dN/d\eta=2700$ (squares). The bars indicate the root-mean-square of the distribution in each E_T bin. The dashed line is a fit to the HIJING fake jets. A clear separation between the fake jets and embedded jets is seen over all E_T . The larger Σj_T for the fake jets indicates that they have a broader energy distribution than the embedded jets.

Fig. 4. The jet E_T -independent cut variable $\sigma_{\Sigma j_T}$, the number of σ from the fake jet mean (see Eqn. 3) for two different jet E_T bins 40-60 GeV (left) and 60-80 GeV (right). There is clear separation between the embedded jets (dashed line) compared to the fake jets (solid line).

Fig. 5. Fake jet rejection vs jet reconstruction efficiency. Each point represents a different cut in $\sigma_{\Sigma j_T}$ from rejecting $\sigma_{\Sigma j_T} > -1$ (lower right) to $\sigma_{\Sigma j_T} > -4$ (upper left).

4 Fake jet rejection

Rejection of fake jets is maximized when exploiting the differences between the embedded and fake jets. Figure 2 shows a general feature of fake jets by comparing two jets with the same reconstructed jet E_T ($= 57$ GeV). The jet in the left panel is an embedded PYTHIA jet and the jet in the right panel is reconstructed from the hard-cut HIJING events. Even though the fragmentation of the PYTHIA jet is not uniform in η and ϕ , a clear core is seen. The fake jet from the hard-cut HIJING event is a cone which stabilized around three towers at large angle to the reconstructed jet axis and no core exists. Such a structure is generally indicative of the jets from the hard-cut HIJING events: little to no core and energy at large angles from the jet axis.

The variable used to discriminate against fake jets is Σj_T , which is constructed to give larger weight to energies at large angle with respect to the jet direction. It is defined

as

$$\Sigma j_T = \sum_{\text{cell} \in \text{jet}} E_{T,\text{cell}} \sin R_{\text{cell}} \quad (1)$$

where $E_{T,\text{cell}}$ is the E_T with respect to the beam and R_{cell} is the angle (in ϕ and η) of the cell with respect to the jet. It has a trivial jet E_T dependence. The definition can be rearranged to yield

$$\Sigma j_T = \langle \sin R \rangle E_{T,\text{jet}} \quad (2)$$

where $\langle \sin R \rangle = \Sigma_{\text{cell}} E_{T,\text{cell}} \sin R_{\text{cell}} / E_{T,\text{jet}}$ is the energy weighted average of $\sin R$. Therefore, broad distributions would have a larger Σj_T than narrow distributions at the same E_T . Figure 3 shows the jet E_T dependence of Σj_T . It is linear for the fake jets measured from hard-cut HIJING events. A rising trend is also observed in the embedded jets, but, because jets become more collimated with increasing E_T , $\langle \sin R \rangle$ decreases with increasing E_T , and, therefore, the rising trend of Σj_T increases more slowly at high E_T . This has the effect that the discrimination between real and fake jets becomes more effective with increasing jet E_T .

Because of the E_T dependence of Σj_T , the applied cut is an E_T -independent quantity: the number of RMS from the fake-jet mean, defined as

$$\sigma_{\Sigma j_T} = \frac{\Sigma j_T - \langle \Sigma j_T \rangle(E_T)}{\sigma(E_T)} \quad (3)$$

where $\langle \Sigma j_T \rangle(E_T)$ and $\sigma(E_T)$ are the E_T -dependent mean and RMS, respectively, fitted to the hard-cut HIJING jets from Figure 3. Figure 4 shows the distribution of $\sigma_{\Sigma j_T}$ for two different jet E_T bins for embedded and fake jets. By definition the fake jets have a mean of zero and an RMS of 1 while the embedded jets have an obviously smaller mean in this variable. The rate of fakes compared to reconstructed embedded jets is also seen in these plots as well as its strong E_T dependence.

Because of the clear separation between the embedded and fake jets, a cut can be applied to reject fake jets at

Fig. 6. The E_T -dependent ratio of $\langle \Sigma_{jT} \rangle$ in PYQUEN jets to embedded jets (black circles) compared to fake HIJING jets to embedded jets (red squares) (from Figure 3). No difference is observed between the quenched and unquenched jets and it is much less than the difference between the fake and embedded jets.

a desired level. However, since the distributions overlap, there is a trade-off between fake jet rejection and efficiency loss. For example, the cut applied in Figure 1 is to reject jets with $\sigma_{\Sigma_{jT}} > -2.5$. For both E_T bins shown in Figure 4 this cut is not only effective in rejecting nearly all fake jets but also results in a sizeable loss of real jets. Figure 5 shows the anti-correlation between the rejection of fake jets and the reconstruction efficiency of embedded jets. In the end the statistics and the desired purity of the data sample will dictate what cut will be applied in real data (see Section 5.2).

5 Results and Discussion

The variable Σ_{jT} has been shown to be effective at rejecting fake, reconstructed cone jets from HIJING events. In this section the effect of energy loss on the rejection and evaluation of the fake jet rate with real data are discussed.

5.1 Effect of energy loss

In radiative energy loss, the energy profile of a given jet is modified jet-by-jet, and on average the energy profile is expected to show large modification [21]. Because the Σ_{jT} is a shape cut, it is possible that such a cut could bias results from measuring the modification of the energy profile of a jet.

An estimate of the effect can be obtained using Equation 2 and assuming a Gaussian distribution of energy within a jet. For a Gaussian with an RMS of ~ 0.2 , then $\langle \sin R \rangle \sim \langle R \rangle$. At a fixed jet E_T the difference between embedded and fake $\langle \Sigma_{jT} \rangle$ then is directly related to the difference between $\langle R \rangle$. From Figure 3, at 50 GeV the fake jet $\langle \Sigma_{jT} \rangle$ is twice that of the embedded jet. Therefore, $\langle R \rangle$ of the fake jet is twice that of the embedded jet. This is

quite a large change for a jet with an RMS of 0.2 to one with 0.4. Such a difference between vacuum and medium modified shape may be expected for 50 GeV gluon jets [21].

An attempt at studying the energy loss effect on the rejection of Σ_{jT} has been done by simulating and reconstructing a set of PYQUEN [22] jets in the ATLAS detector. PYQUEN is a set of routines which modifies PYTHIA partons by energy loss and including the radiated gluons prior to fragmentation. The events were generated assuming $b=0$ fm and they were not embedded into HIJING. Figure 6 shows the ratio of $\langle \Sigma_{jT} \rangle$ as a function of E_T (*i.e.* Figure 3) for quenched to unquenched jets (circles) and for hard-cut HIJING jets to embedded jets (squares). Little change between the quenched and unquenched jets is observed in contrast to the large difference between the fake and embedded $\langle \Sigma_{jT} \rangle$.

The jet energy profile in PYQUEN jets are modified, but not to the same extent as those predicted in Ref. [21], leading to much less change in $\langle R \rangle$. These results were produced after a simulation through the ATLAS calorimeter. It is possible that the segmentation is also coarse enough to smear any effect generated by PYQUEN. It should be clear, however, that because Σ_{jT} is a shape variable, it may show different sensitivities to different jet profiles. The final resolution of how sensitive must wait for analysis of real data.

5.2 Rejection in data

Determining the absolute rate of fake jets in real data, regardless of the rejection variable, can be done by studying the $\Delta\phi$ distribution of the pairs of reconstructed jets. This is a useful variable because 1) the position resolution of jets is good, 2) it has a clear signal peak at $\Delta\phi = \pi$, and 3) fake jets will be randomly associated with other real or fake jets in the events and result in a pedestal. The rejection variable distribution should be different for different regions of $\Delta\phi$.

This is the case for $\sigma_{\Sigma_{jT}}$. Figure 7 shows the distribution of all jets pairs with $E_T^A > 60$ GeV correlated with with $E_T^B > 40$ GeV with different $\sigma_{\Sigma_{jT}}$ cuts applied. For the successively hard $\sigma_{\Sigma_{jT}}$ cuts the pedestal is suppressed. The stars indicate the cut used in Figure 1 which removes a significant fraction of fake jets. With the tightest cut, the signal peak at $\Delta\phi = \pi$ becomes slightly narrower. This may indicate that the hardest cut removes of the radiated jets in a 3-jet event.

6 Summary

A large fake rate of cone jets from HIJING events is observed, exceeding the expected p+p jet rate at low E_T . They result from stable cones being fitted to random and correlated background fluctuations. The variable Σ_{jT} has been used to identify and reject these fake jets. It is shown that this variable is insensitive to the effects of energy loss

Fig. 7. $\Delta\phi$ distribution between reconstructed jets with $E_T^A > 60$ GeV and $E_T^B > 40$ GeV for different $\sigma_{\Sigma l_T}$ cuts.

on jets. It is conceivable that neither the extreme fluctuations nor the characteristics of fake jets (broader, large angle energy distribution) generated in HIJING are observed in the data. In fact, the fake rate will strongly depend on the model of the background and, indeed, will require measurement in the data itself. Even so, because correlated and random fluctuations can produce stable cone jets, it is necessary for any jet analysis in heavy ion collisions at RHIC or the LHC to demonstrate a lack of contamination of such jets.
